### 1 Hashing

(a) Let  $\mathcal{H} = \{H_s : \{0,1\}^{2n} \rightarrow \{0,1\}^n\}_{s \in \{0,1\}^\lambda}$  be a family of collision-resistant hash functions compressing  $2n$  bits into  $n$  bits. Answer the following questions.

(i) Show that  $\mathcal{H}$  is a seeded one-way function in the following sense: for all PPT adversaries  $\mathbf{A}$  there exists a negligible function  $\nu : \mathbb{N} \rightarrow [0, 1]$  such that

$$\mathbb{P}[H_s(x') = y : s \leftarrow \{0,1\}^\lambda; x \leftarrow \{0,1\}^{2n}; y \leftarrow H_s(x); x' \leftarrow \mathbf{A}(s, y)] \leq \nu(n)$$

SOL

Figure 1: Base an attack to CR  $\mathcal{H}$  family, assuming the existence of a PPT attacker  $\mathcal{A}$ , able to win the seeded one-way function Game with non negligible probability.

Assume there exists a PPT attacker  $\mathcal{A}$  that given a value  $y = H_s(x)$ , with  $s \leftarrow_{\$} \{0,1\}^\lambda$  and  $x \leftarrow_{\$} \{0,1\}^{2n}$ , finds a pre-image  $x' : H_s(x) = H_s(x')$  with non negligible probability  $\geq \frac{1}{p(n)}$  for some  $p(n) \in \text{poly}(n)$ . Then we can build on top of  $\mathcal{A}$  an attacker  $\mathcal{A}^*$  able to break the collision resistance of  $\mathcal{H}$ .

In particular, the challenger selects and fixes a seed  $s$ ;  $\mathcal{A}^*$  fixes a value  $x$  and forwards to  $\mathcal{A}$  the value  $y = H_s(x)$ ;  $\mathcal{A}$  returns a value  $x'$  and the tuple  $(x, x')$  is forwarded to the challenger: the game is won if  $x \neq x'$  and  $H_s(x) = H_s(x')$ . Now, by construction, we know that  $\mathcal{A}$  "inverts"<sup>1</sup>  $y$  with probability  $\geq \frac{1}{p(n)}$ . We also know that the domain of  $\mathcal{H}$  is the set of  $2n$ -bit strings, while its co-domain is the set of  $n$ -bit strings: this implies that the expected value of elements  $x : H_s(x) = y$ , once we fix  $y$  and  $s$ , is  $2^n$ , thus implying

<sup>1</sup>with some abuse, we mean that it finds a valid preimage of  $y$ .

that the probability for the attacker  $\mathcal{A}$  to output a value  $x'$  equal to  $x$  is only negligible ( $= 2^{-n}$ ). These two considerations allow to conclude that  $\mathcal{A}^*$  outputs a valid and colliding pair  $(x, x')$  with probability  $\geq \frac{1}{p(n)}(1 - 2^{-n}) \in \text{poly}(n)$ .  $\square$

- (ii) What happens in case the set of functions  $\mathcal{H}$  is not compressing (i.e., the domain of each function  $H_s$  is also  $\{0, 1\}^n$ ? Does collision resistance imply one-wayness in this case?

**SOL** Consider  $H_s(x) := x \oplus \text{pad}(s)$ , where  $\text{pad} : \{0, 1\}^\lambda \rightarrow \{0, 1\}^n$  is public padding function<sup>2</sup>. Then it is easy to see that  $\mathcal{H}$  is collision resistant, since there is no collision at all (for each  $s$ ,  $H_s(\cdot)$  defines a permutation). By the way, this family of functions is definitely not one way; it is easily invertible, since the seed  $s$  is public in the game, i.e. it is known to the adversary too: indeed, given  $y = H_s(x) = \text{pad}(s) \oplus x$ , the attacker outputs  $\mathcal{A}(s, y) = y \oplus \text{pad}(s) = \text{pad}(s) \oplus \text{pad}(s) \oplus x = x$ .  $\square$

- (b) Let  $\mathcal{H} = \{H_s : \{0, 1\}^{4n} \rightarrow \{0, 1\}^{2n}\}_{s \in \{0, 1\}^\lambda}$  and  $\mathcal{H}' = \{H'_s : \{0, 1\}^{2n} \rightarrow \{0, 1\}^n\}_{s \in \{0, 1\}^\lambda}$  be families of collision-resistant hash functions. Analyse the following candidate hash function family compressing  $4n$  bits into  $n$  bits:  $\mathcal{H}^* := \{H_{s_1, s_2}^* : \{0, 1\}^{4n} \rightarrow \{0, 1\}^n\}_{s_1, s_2 \in \{0, 1\}^\lambda}$  such that  $H_{s_1, s_2}^*(x) = H'_{s_2}(H_{s_1}(x))$  for  $s_1, s_2 \leftarrow_{\$} \{0, 1\}^\lambda$ .

**SOL**

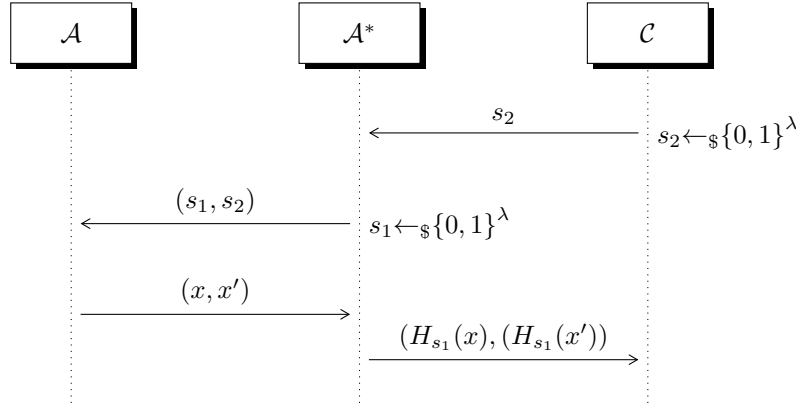

Figure 2: Base an attack to CR  $\mathcal{H}'$  family on top of an attacker  $\mathcal{A}$  to the collision resistance of  $\mathcal{H}^*$ .

Let assume that  $\mathcal{H}^*$  is not collision resistant: this means that, by definition, there exists some PPT attacker  $\mathcal{A}$  that, given two values as seed  $s_1, s_2$ , is able to find, with non negligible probability, a valid pair  $(x, x')$  such that  $H_{s_1, s_2}^*(x) = H_{s_1, s_2}^*(x')$ , with  $x \neq x', x, x' \in \{0, 1\}^{4n}$ . If this is the case we can try to build an attacker  $\mathcal{A}^*$  to break the collision resistance of  $\mathcal{H}'$ . Note that the challenger fixes a seed  $s_2$  and waits for the attacker to find a collision;  $\mathcal{A}^*$  randomly selects and fixes a seed  $s_1 \in \{0, 1\}^\lambda$  and uses  $\mathcal{A}$  in order to find a pair  $(x, x')$ . By assumption, this pair is such that  $H_{s_1, s_2}^*(x) = H_{s_1, s_2}^*(x')$  with non negligible probability  $\geq \frac{1}{p(n)}$ , for some  $p(n) \in \text{poly}(n)$ .

But if  $\mathcal{A}$  is successful (i.e.  $H_{s_1, s_2}^*(x) = H_{s_1, s_2}^*(x')$ ), either (i)  $H_{s_1}(x) = H_{s_1}(x')$  or (ii)  $H_{s_1}(x) \neq H_{s_1}(x')$ . Case (i) can happen only with negligible probability  $\epsilon(n)$ , otherwise we could use  $\mathcal{A}$  to build a PPT attacker to break the collision resistance of  $\mathcal{H}$ . Instead case (ii) guarantees that the pair is valid to build a successful attack to  $\mathcal{H}'$ : in both situations we come to an absurd given our initial assumptions.  $\square$

<sup>2</sup>e.g.  $\text{pad}(s) := s || 0^{n-\lambda}$ .

## 2 Number Theory

- (a) Recall that the CDH problem asks to compute  $g^{ab}$  given  $(g, g^a, g^b)$  for  $(G, g, q) \leftarrow \text{GroupGen}(1^\lambda)$  and  $a, b \leftarrow \mathbb{Z}_q$ . Prove that the CDH problem is equivalent to the following problem: given  $(g, g^a)$  compute  $g^{a^2}$ , where  $(G, g, q) \leftarrow \text{GroupGen}(1^\lambda)$  and  $a \leftarrow \mathbb{Z}_q$ .

**SOL** For sake of simplicity, let us call SCDH the problem defined above (i.e. compute  $g^{a^2}$ , given a tuple  $(\mathbb{G}, g, q, g^a)$ ). We have to prove that both  $\text{CDH} \Rightarrow \text{SCDH}$  and  $\text{SCDH} \Rightarrow \text{CDH}$ .

**(CDH  $\Rightarrow$  SCDH)** given some  $g^a$  it is easy to see that this is equivalent to solve  $\text{CDH}(g, g^a, g^a) = g^{aa} = g^{a^2}$

**(SCDH  $\Rightarrow$  CDH)** given  $(g^a, g^b)$ , we can compute  $\frac{\text{SCDH}(g^{a+b})}{\text{SCDH}(g^a) \cdot \text{SCDH}(g^b)} = \frac{g^{a^2+2ab+b^2}}{g^{a^2} \cdot g^{b^2}} = g^{2ab}$ : at this point we need to compute the square root of such a value: generally speaking this operation cannot be done efficiently; however, there are some groups where computing the square root can be done very easily (e.g. cyclic groups or when the order  $q$  is odd). For example, consider the case for  $q$  odd: it holds that  $(g^{2ab})^{\frac{q+1}{2}} = 1 \cdot (g^{2ab})^{\frac{1}{2}} = g^{ab}$ .

□

- (b) Let  $f_{g,p} : \mathbb{Z}_{p-1} \rightarrow \mathbb{Z}_p^*$  be the function defined by  $f_{g,p}(x) := g^x \bmod p$ . Under what assumption is  $f_{g,p}$  one-way? Prove that the predicate  $h(x)$  that returns the least significant bit of  $x$  is not hard-core for  $f_{g,p}$ .

**SOL** The function  $f_{g,p}(\cdot)$  is one-way if  $g$  is a generator of  $\mathbb{Z}_p^*$ ,  $p$  is prime and under the DL assumption. First of all we know that this function is efficiently computable: this is a requirement for all OWF. On the contrary it is hard to "invert", i.e. to find a value  $x' : f(x) = f(x')$ . Indeed, given  $y = g^x \bmod p$ , a PPT attacker should find a value  $x' : g^x \bmod p = g^{x'} \bmod p$ . But this is possible if and only if  $x - x' \equiv 0 \bmod (p-1)$ .

Note that an element  $g^x \in \mathbb{QR}_p$  if and only if the least significant bit of the exponent  $x$  is 0. Without loss of generality, indeed, we assume  $x \in \{0, 1\}^t$ : this means that  $x$  can be written as  $\sum_{i=0}^t x_i \cdot 2^i$ . Given  $f_{g,p}(x) = g^x \bmod p = g^{\sum_{i=0}^t x_i \cdot 2^i} \bmod p$ , we can check whether  $f_{g,p}(x) \in \mathbb{QR}_p$  or not, in order to leak the least significant bit of  $x$ .

The last step is to find a necessary and sufficient condition to check whether an element  $y$  is a quadratic residue modulo  $p$  or not.

We can compute  $s = y^{\frac{p-1}{2}}$ ; if  $s \equiv 1 \bmod p$ , then  $y$  is a quadratic residue; otherwise it is not.

**( $\Rightarrow$ )** If  $y$  is a quadratic residue, then it holds that  $y = (g^\alpha)^2 = g^{2\alpha}$ , for some  $\alpha$ . But then:  $y^{\frac{p-1}{2}} = g^{\alpha(p-1)} = (g^{p-1})^\alpha = 1^\alpha = 1 \bmod p$ .

**( $\Leftarrow$ )** If it holds that  $y^{\frac{p-1}{2}} \equiv 1 \bmod p$ , then  $g^{\frac{x(p-1)}{2}} \equiv 1 \bmod p$ . This implies that  $\frac{x(p-1)}{2} \equiv 0 \bmod (p-1)$  that can be satisfied if and only if  $x$  is even. Finally, we conclude that  $y = g^x = (g^{\frac{x}{2}})^2$ , proving that  $y$  is a quadratic residue.

□

- (c) Let  $N$  be the product of 5 distinct odd primes. If  $y \in \mathbb{Z}_N^*$  is a quadratic residue, how many solutions are there to the equation  $x^2 = y \bmod N$ ?

**SOL**  $x^2 \equiv y \bmod N$  means that  $x^2 \equiv y \bmod p_1 \cdot p_2 \cdot p_3 \cdot p_4 \cdot p_5$ . This implies that there exists a  $k \in \mathbb{Z}$  such that  $y = x^2 + k \prod_{i=1}^5 p_i$ . If we define  $y_i := y \bmod p_i$ , we can rewrite the

equation as  $y_i \equiv x^2 \pmod{p_i}, i \in \{1, \dots, 5\}$ . This system of equation can be safely rewritten as  $x^2 \equiv y_i \pmod{p_i}$ , but now, for the Chinese remainder theorem, we know that once we fix the values  $y_i$  for all  $i$ , there exists a unique solution satisfying the system<sup>3</sup>. Note that each  $y_i$  is such that it is equivalent (modulo  $p_i$ ) to  $x_i^2$ , where  $x_i := x \pmod{p_i}$ . Each of the 5 equations has two distinct solutions  $\pm \alpha_i$ , since  $\alpha_i \not\equiv -\alpha_i \pmod{p_i}$ , because  $p_i \neq 2, \forall i$ . And this proves that there are  $2^5$  distinct systems, each of these with a unique solution (for CR theorem). This implies that the number of solutions to the original equation is  $2^5 = 32$ .  $\square$

### 3 Public-Key Encryption

- (a) Show that for any CPA-secure public-key encryption scheme for single-bit messages, the length of the ciphertext must be super-logarithmic in the security parameter.

**SOL** If the length of the ciphertext is not super-logarithmic, we know that the number of possible ciphertexts is at most  $\lambda^c$  for some constant  $c$ . The attacker can compute a ciphertext  $c_0$  associated to bit 0, then waits for the challenge  $c_b^*$  and compares the two values: if they are equal it returns 0, otherwise returns 1. Now, if the challenger selects  $b = 0$ , the attacker wins with probability at least  $\lambda^{-c}$ , otherwise wins with probability 1. Taking the weighted average we have a winning probability  $w \geq \frac{1}{2} + \frac{1}{2\lambda^c}$ .

But then  $|w - \frac{1}{2}| \geq \frac{1}{2\lambda^c}$ , where  $2\lambda^c \in \text{poly}(\lambda)$ .  $\square$

- (b) Let  $\Pi = (\text{KGen}, \text{Enc}, \text{Dec})$  be a PKE scheme with message space  $\{0, 1\}$  (i.e., for encrypting a single bit). Consider the following natural construction of a multi-bit PKE scheme  $\Pi' = (\text{KGen}', \text{Enc}', \text{Dec}')$  with message space  $\{0, 1\}^t$ , for some polynomial  $t = t(\lambda)$ : (i) The key generation stays the same, i.e.  $\text{KGen}'(1^\lambda) = \text{KGen}(1^\lambda)$ ; (ii) Upon input  $m = (m[1], \dots, m[t]) \in \{0, 1\}^t$  the encryption algorithm  $\text{Enc}'(pk, m)$  outputs a ciphertext  $c = (c_1, \dots, c_t)$  where  $c_i \leftarrow_{\$} \text{Enc}(pk, m[i])$  for all  $i \in [t]$ ; (iii) Upon input a ciphertext  $c = (c_1, \dots, c_t)$  the decryption algorithm  $\text{Dec}'(sk, c)$  outputs the same as  $(\text{Dec}(sk, c_1), \dots, \text{Dec}(sk, c_t))$ .

- (i) Show that if  $\Pi$  is CCA1 secure, so is  $\Pi'$ .

**SOL** In order to prove the above claim, it is convenient to use the hybrid argument: note that the goal is to prove that for all PPT adversaries  $\mathcal{A}$ , it holds that  $\text{Game}_{\Pi, \mathcal{A}}^{\text{CCA-1}}(\lambda, 0) \approx_c \text{Game}_{\Pi, \mathcal{A}}^{\text{CCA-1}}(\lambda, 1)$ .

In particular let us define a set of intermediate hybrid games  $\text{Hyb}_i$ , where the adversary is given access to the decryption oracle (together with all the public parameters to make encryptions too, of course) exactly as each of the two games above: the difference is that, when the adversary commits the challenge tuple  $(m_0, m_1)$ , the challenge ciphertext  $c^*$  is such that its  $j$ -th component is sampled from  $\text{Enc}(pk, m_0[j])$  if  $i \leq j$ , otherwise comes from  $\leftarrow_{\$} \text{Enc}(pk, m_1[j])$ .

Note that once we fix the pair  $(m_0, m_1)$ , the only difference between two hybrids  $\text{Hyb}_i$  and  $\text{Hyb}_{i+1}$  is in the distribution of the  $i$ -th component of the challenge  $c^*$ . It is easy to see that  $\text{Hyb}_1 \equiv \text{Game}_{\Pi, \mathcal{A}}^{\text{CCA-1}}(\lambda, 0)$  and  $\text{Game}_{\Pi, \mathcal{A}}^{\text{CCA-1}}(\lambda, 1) \equiv \text{Hyb}_t$ .

Here for simplicity we give the distribution of the challenge ciphertext  $c^*$  for each hybrid game:

- $\text{Hyb}_1 \rightarrow (\text{Enc}(pk, m_0[1]), \text{Enc}(pk, m_0[2]), \dots, \text{Enc}(pk, m_0[t])) \equiv \text{Enc}'(m_0)$
- $\text{Hyb}_2 \rightarrow (\text{Enc}(pk, m_1[1]), \text{Enc}(pk, m_0[2]), \dots, \text{Enc}(pk, m_0[t]))$
- ...

<sup>3</sup>with a simple substitution, we put  $T := x^2$  and can apply the theorem.

- $\text{Hyb}_{t-1} \rightarrow (\text{Enc}(pk, m_1[1]), \dots, \text{Enc}(pk, m_1[t-1]), \text{Enc}(pk, m_0[t]))$
- $\text{Hyb}_t \rightarrow (\text{Enc}(pk, m_1[1]), \dots, \text{Enc}(pk, m_1[t-1]), \text{Enc}(pk, m_1[t])) \equiv \text{Enc}'(m_1)$

Imagine there exists a PPT distinguisher between two hybrids  $\text{Hyb}_i$  and  $\text{Hyb}_{i+1}$  (for some  $i$ ). If this is the case, we can build a PPT attacker  $\mathcal{A}$  to break the CCA1-security of  $\Pi$ . Indeed, we can ask the challenger to give us an encryption  $c_b^*$  of a bit  $b$ . Then we pass to the distinguisher a value  $c$  such that the first  $i$  components are  $\leftarrow_{\$} \text{Enc}(pk, m_0[j]), \forall j < i$ , its  $i$ -th component is equal to  $c_b^*$  and then the last  $t-i-1$  components are  $\leftarrow_{\$} \text{Enc}(pk, m_1[j])$ . We then forward to the challenger the same bit returned by the distinguisher and we retain the same non negligible advantage<sup>4</sup>. This proves that  $\forall i, \text{Hyb}_i \approx_c \text{Hyb}_{i+1}$  which implies that also  $\text{Game}_{\Pi, \mathcal{A}}^{\text{CCA}^{-1}}(\lambda, 0) \approx_c \text{Game}_{\Pi, \mathcal{A}}^{\text{CCA}^{-1}}(\lambda, 1)$ .  $\square$

- (ii) Show that, even if  $\Pi$  is CCA2 secure,  $\Pi'$  is not CCA2 secure.

**SOL** Even if the original scheme is CCA2, it is very simple to break the CCA2-security of  $\Pi'$ : the attacker obtains a ciphertext  $c_b^*$  where the first bit of  $m_0^*$  is 0 as well as the first bit of  $m_1^*$ . Now it produces another ciphertext for the bit 0:  $x := \text{Enc}(0)$  such that  $x$  is different from the encryption of the first bit of  $m_b^*$ , and then asks for the decryption of  $c' = (x || c_b^{**5})$ , and finally returns the decision bit  $b' : m_{b'}^* = \text{Dec}(c')$ , winning with probability 1.  $\square$

- (c) Consider the following variant of El Gamal encryption. Let  $p = 2q + 1$ , let  $\mathbb{G}$  be the group of squares modulo  $p$  (so  $\mathbb{G}$  is a subgroup of  $\mathbb{Z}_p^*$  of order  $q$ ), and let  $g$  be a generator of  $\mathbb{G}$ . The private key is  $(\mathbb{G}, g, q, x)$  and the public key is  $(\mathbb{G}, g, q, h)$ , where  $h = g^x$  and  $x \in \mathbb{Z}_q$  is chosen uniformly. To encrypt a message  $m \in \mathbb{Z}_q$ , choose a uniform  $r \in \mathbb{Z}_q$ , compute  $c_1 := g^r \bmod p$  and  $c_2 := h^r + m \bmod p$ , and let the ciphertext be  $(c_1, c_2)$ . Is this scheme CPA-secure? Prove your answer.

**SOL** This scheme is not CPA-secure. Indeed, note that in order to compute  $c_1$  we add an element  $h^r \in \mathbb{G}$  to the message  $m \in \mathbb{Z}_q$ . This means that  $c_2 \in \mathbb{Z}_p^*$  but not necessarily it is an element of  $\mathbb{G}$ : in particular, an attacker could exploit the fact that choosing uniformly a message  $m \leftarrow_{\$} \mathbb{Z}_q$ ,  $\mathbb{P}[c_2 \in \mathbb{G} : c_2 = h^r + m \bmod p; h^r \in \mathbb{G}] = \frac{q}{2q+1}$ , because among all the  $2q+1$  elements of the group, only  $q$  of them are squares (and then belong to  $\mathbb{G}$ ).

Note also that when  $m = 0$ ,  $c_2 = h^r + m = h^r \Rightarrow c_2 \in \mathbb{G}$ .

So our attacker can use these two messages  $m_0^* = 0$  and  $m_1^* \leftarrow_{\$} \mathbb{Z}_q$  and can receive the challenge  $c_b^*(c_1^*, c_2^*)$ : if  $c_2^* \in \mathbb{G}$  it outputs 0, otherwise outputs 1. Note that if  $b = 1$ , the attacker wins with probability 1; otherwise it wins with probability  $\frac{q+1}{2q+1}$ . But this is enough to retain a non negligible advantage (the winning probability is  $w = \frac{1}{2} + \frac{q+1}{2(2q+1)} \Rightarrow |w - \frac{1}{2}|$  is non negligible in  $\lambda$ ).  $\square$

## 4 Signature Schemes

- (a) Consider a weaker variant of UF-CMA in which the attacker receives  $(pk, m^*)$  at the beginning of the experiment, where the message  $m^*$  is uniformly random over  $\mathbb{Z}_N^*$ , and thus it has to forge on  $m^*$  after possibly seeing polynomially-many signatures  $\sigma_i$  on uniformly random messages  $m_i \leftarrow_{\$} \mathbb{Z}_N^*$  chosen by the challenger. Call this notion random-message unforgeability under random-message attacks (RUF-RMA).

<sup>4</sup>this proof is not valid if  $m_0[i] = m_1[i]$ : but in such a scenario a distinguisher between  $\text{Hyb}_i$  and  $\text{Hyb}_{i+1}$  cannot even exist, since the  $i$ -th component is sampled from the same distribution and then the two distributions are equivalent.

<sup>5</sup>it is  $c_b^*$  without the first block, the one corresponding to the encryption of the first bit of  $m_b^*$

Formalize the above security notion, and prove that UF-CMA implies RUF-RMA but not viceversa.

**SOL** Given a signature scheme  $\Pi := (\text{KGen}, \text{Sign}, \text{Vrfy})$ , let consider the following game  $\text{Game}_{\Pi, \mathcal{A}}^{\text{RUF-RMA}}(\lambda)$ :

- (a) the challenger  $\mathcal{C}$  generates  $(pk, sk) \leftarrow_{\$} \text{KGen}(1^\lambda)$
- (b) the challenger  $\mathcal{C}$  fixes a message  $m^* \leftarrow_{\$} \mathbb{Z}_N^*$  and forwards to  $\mathcal{A}$  both the public key  $pk$  and the message  $m^*$
- (c)  $\mathcal{A}$  has access to oracle  $O_1(sk)$ : this oracle samples a message  $m_i \leftarrow_{\$} \mathbb{Z}_N^*$  and returns  $(m_i, \sigma_i)$  such that  $\text{Vrfy}(pk, (m_i, \sigma_i)) = 1$
- (d)  $\mathcal{A}$  forges the signature  $\sigma^*$
- (e) the output of the game is  $\text{Vrfy}(pk, (m^*, \sigma^*))$  (i.e. 1 in case of win, 0 otherwise)

We say that a scheme  $\Pi$  is RUF-RMA-secure if  $\forall$  PPT attackers  $\mathcal{A}$ ,  $\exists \epsilon(\lambda) \in \text{negl}(\lambda)$ :

$$\mathbb{P}[\text{Game}_{\Pi, \mathcal{A}}^{\text{RUF-RMA}}(\lambda) = 1] \leq \epsilon(\lambda)$$

**(UF-CMA  $\Rightarrow$  RUF-RMA)** Assume that a scheme  $\Pi := (\text{KGen}, \text{Sign}, \text{Vrfy})$  is not RUF-RMA: then there exists a PPT attacker  $\mathcal{A}$  able to forge, with non negligible probability, a valid signature  $\sigma^*$  for the message  $m^*$  fixed by the challenger. If this is true, we can build on top of  $\mathcal{A}$  an attacker  $\mathcal{A}^*$  able to forge a valid pair and break UF-CMA-security too.

First of all, in this reduction,  $\mathcal{A}^*$  forwards to  $\mathcal{A}$  all the public parameters. Moreover, it randomly selects a message  $m^*$  and relays this to  $\mathcal{A}$ :  $m^*$  simulates the random challenge. At this point, the attacker  $\mathcal{A}$  can start querying the oracle  $O_1$ ; but  $\mathcal{A}^*$  can simulate very easily these queries, simply picking a message at random  $m_i \leftarrow_{\$} \mathbb{Z}_N^*$  and asking the challenger  $\mathcal{C}$  to forge a valid signature  $\sigma_i$ : the pair  $(m_i, \sigma_i)$  is then forwarded to  $\mathcal{A}$ . After potentially a polynomial number of these oracle calls,  $\mathcal{A}$  is ready to forge a signature  $\sigma^*$  and  $\mathcal{A}^*$  forwards to  $\mathcal{C}$  the pair  $(m^*, \sigma^*)$ , retaining the same non-negligible advantage.

**(RUF-RMA  $\not\Rightarrow$  UF-CMA)** The textbook version of RSA signatures is RUF-RMA (see next exercise), however it is not UF-CMA as proved in class.  $\square$

- (b) Recall the textbook-version of RSA signatures.

$\text{KGen}(1^\lambda)$ : Run  $(N, e, d) \leftarrow_{\$} \text{GenModulus}(1^\lambda)$ , and let  $pk = (e, N)$  and  $sk = (N, d)$ .

$\text{Sign}(sk, m)$ : Output  $\sigma = m^d \bmod N$ .

$\text{Vrfy}(pk, m, \sigma)$ : Output 1 if and only if  $\sigma^e \equiv m \bmod N$ .

Prove that the above signature scheme  $\Pi = (\text{KGen}, \text{Sign}, \text{Vrfy})$  satisfies RUF-RMA under the RSA assumption.

**SOL** Assume not: then there exists a PPT attacker  $\mathcal{A}$  (against RUF-RMA of  $\Pi$ ), on top of which we can break RSA assumption. In particular, the challenger generates RSA params  $(N, e, d)$  and fixes, at random, a value  $x \leftarrow_{\$} \mathbb{Z}_N^*$  and computes  $y = x^e$ . The attacker  $\mathcal{A}^*$  forwards the public key  $(N, e)$  to  $\mathcal{A}$ ; moreover it fixes  $m^* = y$ . In order to simulate the calls to oracle  $O_1$  it can do the following: generates a signature  $\sigma_i \leftarrow_{\$} \mathbb{Z}_N^*$  and then computes the message  $m_i = \sigma_i^e$  and returns the pair  $(m_i, \sigma_i)$ . Note that such a pair is valid (because  $\sigma_i^e = m_i$  by definition, and since  $\sigma_i$  is chosen at random, also  $m_i$  looks random<sup>6</sup>). We know that  $\mathcal{A}$  forges a valid pair  $(y, \sigma^*)$  with non negligible probability, such that  $\sigma^{*e} = y \Rightarrow \sigma^* = x$ . This concludes the proof.  $\square$

---

<sup>6</sup>this is crucial, otherwise it would not be a valid simulation.

## 5 Actively Secure ID Schemes

Let  $\Pi = (\text{KGen}, \text{P}, \text{V})$  be an ID scheme. Informally, an ID scheme is actively secure if no efficient adversary  $\mathcal{A}$  (given just the public key  $pk$ ) can make  $\text{V}$  accept, even after  $\mathcal{A}$  participates maliciously in poly-many interactions with  $\text{P}$  (where the prover is given both the public key  $pk$  and the secret key  $sk$ ). More formally, we say that  $\Pi$  satisfies active security if for all PPT adversaries  $\mathcal{A}$  there is a negligible function  $\nu : \mathbb{N} \in \{0, 1\}$  such that:

$$\mathbb{P}[\text{Game}_{\Pi, \mathcal{A}}^{\text{mal-id}}(\lambda) = 1] \leq \nu(\lambda),$$

where the game  $\text{Game}_{\Pi, \mathcal{A}}^{\text{mal-id}}(\lambda)$  is defined as follows:

- The challenger runs  $(pk, sk) \leftarrow \text{KGen}(1^\lambda)$ , and returns  $pk$  to  $\mathcal{A}$ .
- Let  $q(\lambda) \in \text{poly}(\lambda)$  be a polynomial. For each  $i \in [q]$ , the adversary can run the protocol  $\Pi$  with the challenger (where the challenger plays the prover and the adversary plays the malicious verifier), obtaining transcripts  $\tau_i \leftarrow \text{P}(pk, sk) \stackrel{?}{=} \mathcal{A}(pk)$ .
- Finally, the adversary tries to impersonate the prover in an execution of the protocol with the challenger (where now the challenger plays the honest verifier), yielding a transcript  $\tau^* \leftarrow \text{P}(pk) \stackrel{?}{=} \text{V}(pk)$ .
- The game outputs 1 if and only if the transcript  $\tau^*$  is accepting, i.e.  $\text{V}(pk, \tau^*) = 1$ .

Answer the following questions.

- (a) Prove that passive security is strictly weaker than active security. Namely, show that every ID scheme  $\Pi$  that is actively secure is also passively secure, whereas there exists a (possibly contrived) ID scheme  $\Pi_{\text{bad}}$  that is passively secure but not actively secure.

**SOL (active  $\Rightarrow$  passive)** Assume not, then there exists some PPT attacker  $\mathcal{A}$  that breaks the passive security of an actively secure scheme  $\Pi$ . If this is true, we can build a new PPT attacker  $\mathcal{A}^*$  that breaks the active security of  $\Pi$ . Indeed, when  $\mathcal{A}$  asks to see some valid transcript  $\tau_i$ , prompting the empty string,  $\mathcal{A}^*$  will simply start a session of the protocol as an **honest**<sup>7</sup> verifier with the challenger acting as the (honest) prover. The final transcript  $\tau_i$  is then forwarded to the original attacker: and this can be done up to a polynomial number of times of course. At this point,  $\mathcal{A}$  impersonates a malicious prover (because it has not the secret key  $sk$ ), directly interacting with the verifier ( $\mathcal{A}^*$ , of course, forwards the messages of  $\mathcal{A}$  to the challenger and then sends its replies back to  $\mathcal{A}$ ). This allows  $\mathcal{A}^*$  to retain the same non negligible advantage of  $\mathcal{A}$  since the reduction is tight.

**(passive  $\not\Rightarrow$  active)** Consider a canonical  $\Sigma$  protocol  $\Pi$ : we define a variant  $\Pi'$  such that the verifier appends a bit  $b$  to its (unique) message  $\beta$  where  $\mathbb{P}[b = 0] = 2^{-\lambda}$ ; if  $b = 0$  (this happens only with negligible probability in  $\lambda$ ) the prover has to send the secret key  $sk$ ; otherwise it follows the original protocol to compute  $\gamma$ <sup>8</sup>. This clearly does not compromise the passive security of  $\Pi'$ , because the attacker should hope to see a transcript where the secret key is leaked, but this happens only with negligible probability since the verifier is honest (it is simulated by the challenger itself); on the contrary, this scheme is not actively secure, because the adversary is allowed to impersonate the verifier in the first part of its attack: then it can easily find out the secret key (needs only one query where it appends  $b = 0$  to some  $\beta$ ) and then it can act as a malicious prover and forge a valid transcript thanks to the leaked key.  $\square$

<sup>7</sup>must behave honestly, for each transcript requested by  $\mathcal{A}$ , in order to perfectly simulate the oracle.

<sup>8</sup>of course  $\text{V}'$  will check the last bit of  $\beta$  and if it is equal to 1, it will run  $\text{V}(\cdot)$ .

- (b) Let  $\Pi' = (\text{KGen}, \text{Sign}, \text{Vrfy})$  be a signature scheme, with message space  $\mathcal{M}$ . Prove that if  $\Pi'$  is UF-CMA, the following ID scheme  $\Pi = (\text{KGen}, \text{P}, \text{V})$  (based on  $\Pi'$ ) achieves active security:

$\text{P}(pk, sk) \Rightarrow \text{V}(pk)$ : The verifier picks random  $m \leftarrow_{\$} \mathcal{M}$ , and forwards  $m$  to the prover. The prover replies with  $\sigma \leftarrow_{\$} \text{Sign}(sk, m)$ , and finally the verifier accepts if and only if  $\text{Vrfy}(pk, m, \sigma) = 1$ .

**SOL** As always, assume not: then if there exists a PPT  $\mathcal{A}$  able to break the active security of  $\Pi$ , we can build on top of it a new attacker  $\mathcal{A}^*$  to break the UF-CMA-security of  $\Pi'$ . In our reduction, we first forward to the original attacker the public key  $pk$  (and, of course, all the public parameters generated by  $\mathcal{C}$ ).

The attacker  $\mathcal{A}$  is allowed in the first phase to interact as a (possibly malicious) verifier: it will start sending some message  $m_i$ , waiting for the prover to reply;  $\mathcal{A}^*$  will forward  $m_i$  to the challenger in order to produce a valid  $\sigma_i$  and then is ready to reply; this allows the attacker  $\mathcal{A}$  to collect some transcript  $\tau_i$ . After polynomially many such queries, it tries to impersonate the prover: so  $\mathcal{A}^*$  will pick a random (and "fresh"<sup>9</sup>, i.e.  $\neq m_i, \forall i$ ) message  $m^*$  and passes it to  $\mathcal{A}$ ; then, a  $\sigma^*$  is forged (valid with probability  $\geq \frac{1}{p(\lambda)}, p(\lambda) \in \text{poly}(\lambda)$ ); the pair  $(m^*, \sigma^*)$  is forwarded to the challenger and the winning condition is that  $\sigma^*$  is a valid signature of  $m^*$ . But this directly implies that  $\mathcal{A}^*$  has the same non negligible advantage of the original  $\mathcal{A}$ .  $\square$

- (c) Is the above protocol honest-verifier zero-knowledge? Prove your answer.

**SOL** In order to be HVZK, it should exist a simulator  $S$  such that  $\{pk, sk, \text{Trans}(pk, sk)\} \approx_c \{pk, sk, S(pk)\}$ . Note that this simulator is given in input only the public key  $pk$ . But if such  $S$  exists, the underlying signature scheme  $\Pi$  cannot be UF-CMA: this because  $S$  is able to produce valid pairs  $(m_i, \sigma_i)$  in a way that is (computationally) indistinguishable from  $\text{Trans}(pk, sk)$  and in particular it can forge a valid pair in  $\text{Game}_{\Pi'}^{\text{UF-CMA}}(\lambda)$  too.

If, instead, we remove the UF-CMA assumption of  $\Pi'$ , it could be that for some schemes it is possible to compute pairs  $(m_i, \sigma_i)$  given only  $pk$ : e.g. a possible strategy could be to pick a random  $\sigma_i$  and then find some message  $m_i$  such that  $\text{Vrfy}(pk, (m_i, \sigma_i)) = 1$ . If this is the case, then we can build such a simulator  $S$  and the above protocol is HVZK.  $\square$

---

<sup>9</sup>note that it can do it, since it observes all the queries  $m_i$ .
